#### Abstract

The Flow Shop Scheduling Problem (FSSP) is a problem that is commonly found by master production scheduling planners in Flexible Manufacturing Systems (FMS). The planner should find the optimal scheduling to carry out a set of jobs in order to satisfy the predefined objective (e.g., makespan). All the jobs are processed in a production line composed of a set of shared machines. Furthermore, the jobs are processed in the same sequence. In order to be able to analyze this problem in a better way, this problem needs to be represented adequately for understanding the relationship among the operations that are carried out. Thus, an FMS presenting the FSSP can be modeled by Petri nets (PNs), which are a powerful tool that has been used to model and analyze discrete event systems. Then, the makespan can be obtained by simulating the PN through the token game animation. In this work, we propose a new way to calculate the makespan of FSSP based on timed place PNs.

Keywords: Flow shop scheduling problem; makespan; Petri nets.

## 1. Introduction

Flexible Manufacturing Systems (FMSs) are very important in advancing factory automation due to the ability to adjust to customers' preferences and the

[^0]speed to reconfigure the system. A FMS is a discrete event dynamic system composed of jobs and shared resources [1]. When a manufacturer is designing the master production schedule in a FMS with shared resources, it is common that $\mathrm{s} /$ he has to face the decision about the best sequence of jobs in the FMS in order to carry all operations out in the minimum time [2], [3].

This problem is called the Flow Shop Scheduling Problem (FSSP), which is a combinatorial problem classified as NP-hard [4]. The makespan is the time that all the jobs are processed in the FMS, and it depends on the order that all the tasks are performed.

There have been published several research papers about finding the minimum value of makespan in the FSSP. For instance, a D.S. Palmer proposed a method to find an acceptable sequence in less time than exhaustive search [5]. Another algorithm based on heuristic strategies to find suitable solutions was proposed in reference [6]. Dannenbring performed a similar work, where he proposed eleven heuristics to solve the FSSP [7]. Nawas proposed an algorithm based on the assumption that jobs with higher processing time must be treated first; his algorithm is applied to static and dynamic sequencing environment [8]. In reference [9], Taillard applied taboo search to solve FSSP; moreover, he implemented a parallel version of taboo search to improve the algorithm execution time. Framinan and Leisten proposed a heuristic taking into account the optimization of partial schedules; instead of optimize the whole schedule [10]. Later, Framinan, Leisten and Ruiz-Usano proposed two multi-objective heuristics, whose objectives to solve are makespan and flowtime minimization [11].

Several metaheuristics have been used to find the minimum value for the makespan, such as Simulated Annealing [12],[13]; Taboo Search [14], [15]; Genetic Algorithms [16]-[18]; Ant Colony Optimization [19], [20]; Iterated Local Search [21]; and Particle Swarm Optimization Algorithms [22], [23], [27]. These proposals can find reasonable results in less time than exact methods. The main outcome of these methods is that the global minimum could not be found; however, good approximations are obtained in a short time. Thus, all of them need a way to represent the FSSP in order to calculate the makespan. FSSP modeling should be understandable and able to calculate the makespan of a job operations sequence.

FMSs have been modeled via Petri Nets (PNs) in order to simulate and analyze them. PN theory is adequate to represent in a graphical and mathematical way Discrete Event Systems (DES) such as FMSs, because their dynamic behavior based on event occurrence can be modeled by PN elements (places and transitions) [24]. Moreover, PN theory offers analytical and graphical tools to study the modeled systems, based on the relationship among
the FMS resources denoted as PN elements. In [29], a timed Petri net is applied to model and simulate a production system, which is generated algorithmically.

One important point in search methods is the calculus of the makespan, taking into account a certain processing order of the tasks. In this paper, we propose the use of an timed PN to calculate the makespan taking into account the PN transition firing.

## 2. Flow Shop Scheduling Problem

Scheduling tasks in a FMS is a typical combinatorial problem where it is needed to organize the processing of a set of jobs divided in operations, and each operation is carried out in a shared resource [25], [26].

In the FSSP, given the processing times $p_{j k}$ for each job $j$ on every machine $k$, and a job sequence $S=\left(s_{1}, s_{2}, \ldots, s_{n}\right)$ where $n$ jobs $(j=1,2, \ldots, n)$ will be processed by $m$ machines $(k=1,2, \ldots, m)$, so the aim of FSSP is to find a sequence order for operation processing with the minimum value for the makespan.

For instance, Table 1 shows a FMS with three machines, four jobs, and each job has three serial operations, one for each machine.

Table 1. Operation times in a FMS.

| Machines | Jobs |  |  |  |
| :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{J}_{1}$ | $\mathrm{~J}_{2}$ | $\mathrm{~J}_{3}$ | $\mathrm{~J}_{4}$ |
|  | 96 | 74 | 13 | 71 |
| $\mathrm{M}_{2}$ | 90 | 57 | 5 | 23 |
| $\mathrm{M}_{3}$ | 35 | 91 | 7 | 38 |

Note: Every value is denoted in a time unit.

## 3. Petri Nets Concepts

A PN is a graphical and mathematical tool that has been used to model concurrent, asynchronous, distributed, parallel, non-deterministic, and/or stochastic systems.

The graph of a PN is directed, with weights in their arcs, and bipartite, whose nodes are of two types: places and transitions. Graphically, places are depicted as circles and transition as boxes or bars. PN arcs connect places to transitions or transition to places; it is not permissible to connect nodes of the same type. The state of the system is denoted in PN by the use of tokens, which are assigned to place nodes.

A formal definition of a PN is presented as follows [24].

A Petri net is a 5-tuple, $P N=\left(P, T, F, W, M_{0}\right)$ where:
$P=\left\{p_{1}, p_{2}, \ldots, p_{m}\right\}$ is a finite set of places,
$T=\left\{t_{1}, t_{2}, \ldots, t_{n}\right\}$ is a finite set of transitions,
$F \subseteq\{P \cdot T\} \cup\{T \cdot P\}$ is a set of arcs,
$W=F \rightarrow\{1,2,3, \ldots\}$ is a weight function,
$M_{0}=P \rightarrow\{0,1,2,3, \ldots\}$ is the initial marking, $P \cap T=\varnothing$ and $P \cup T \neq \varnothing$.
The set of places that are connected to a transition is known as input places, which is denoted as $\bullet t$. On the other hand, the places connected from a transition are known as output places, and the set of output places are represented by te.

The token movement through the PN represents the dynamical behavior of the system. In order to change the token position, the following transition firing rule is used [24]:

1. A transition $t \in T$ is enabled if every input place $p \in P$ of t has $w(p, t)$ tokens or more. $w(p, t)$ is the weight of the arc from $p$ to $t$.
2. An enabled transition $t$ will fire if the event represented by $t$ takes place.
3. When an enabled transition $t$ fires, $w(p, t)$ tokens are removed from every input place $p$ of $t$ and $w(t, p)$ tokens are added to every output place $p$ of $t . w(t, p)$ is the weight of the arc from $t$ to $p$.

### 3.1. Timed Place Petri Nets

PN transitions, places, and arcs can be assigned with a time unit, meaning a time delay defined according to a FMS that considers time in its operations.

A Timed Place Petri Net (TPPN) is an extended PN, where a new element is added. It is a six-tuple $T P P N=\left\{P, T, F, W, M_{0}, D\right)$, where the first fifth elements are similar to PN definition presented above, and $D=\left\{d_{1}, d_{2}, \ldots, d_{m}\right\}$ denotes the time-delay for each place $p_{j} \in P$ [28]. Output transitions $t_{i}$ for each $p_{j}$ will be enabled once the time indicated in $p_{j}$ is reached.

### 3.2. Analysis Methods of Petri Nets

In this chapter, we are applying the matrix equation approach as the analytical method of PN theory in order to calculate the makespan of the FMS modeled.

### 3.2.1. Incidence Matrix and State Equation

A $P N$ with $n$ transitions and $m$ places can be expressed mathematically as an $n$. $m$ matrix of integers $A=\left[a_{i j}\right]$. The values for each element of the matrix are
given by: $a_{i j}=a_{i j}{ }^{+}-a_{i j}{ }^{{ }^{j}}$, where $a_{i j}{ }^{+}$is the weight of the arc from $t_{i}$ to $p_{j}$, and $a_{i j}{ }^{-}$is the weight of the arc from $p_{j}$ to $t_{i}$.

The state equation is used to determine the marking of a PN after a transition firing, and it can be written as follows:

$$
\begin{equation*}
M_{k}=M_{k-1}+A^{T} U_{k}, \mathrm{k}=1,2, \ldots \tag{1}
\end{equation*}
$$

where $U_{k}$ is a $n \times 1$ column vector of $n-1$ zeros and one nonzero entries, which represents the transition $t_{j}$ that will fire. The nonzero entry is located in the position $j$ of $U_{k} . A^{T}$ is the transpose of incidence matrix. $M_{k-1}$ is the marking before the firing of $t_{j}$. And $\mathrm{M}_{\mathrm{k}}$ is the reached marking after the firing of $t_{j}$ denoted in $U_{k}$.

### 3.2.2. Reachability Analysis Method

All the possible states that a system can reach from the initial state of a PN can be derived by using the reachability tree or graph [1].

There are two ways to generate the reachability tree of a Petri net from an initial marking: depth-first and breadth-first. In the depth-first strategy, all the enabled transitions are identified and one of them is fired, creating a new marking. If it is a marking that has been created previously or a marking that has no enabled transitions, stop exploring it, and return to the preceding marking; next, continue with the unexplored transitions. Otherwise, from the new marking, identify the enabled transitions and fire one of them. Continue with these steps until all the transitions have been fired and all markings have been generated if the number of markings is finite.

In the second strategy, all the enabled transitions are identified and fired, generating new markings. For every new marking, that is not old or end marking, again identify and fire all the enabled transitions of the same level. Then, repeat the steps described above to the following levels of the reachability tree until all the levels have been explored.

## 4. FSSP modeled by a Timed Place Petri Net

In this work we are proposing a different way to obtain the makespan by using timed place PNs. The main idea is to denote every flow shop operation by a simple PN structure composed of one place denoting the operation time, one input transition $t_{j}$ to place $p_{i}$, and one output transition $t_{j+1}$ from place $p_{i}$. (Figure 1).

Thus, the processing time $\tau$ is stored in the place between the transitions, and it corresponds to the operation time defined in the FSSP. For each operation of job $J_{i}$ performed in machine $M_{i}$ there is a processing time $\tau_{i j}$. (Table 2).

Fig. 1. PN structure denoting one single operation of a job, which is processed in a shared machine during $\tau$ time units.

Table 2. Matrix for operation times in a FMS.

| Machines | Jobs |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
|  | $\mathrm{J}_{1}$ | $\mathrm{~J}_{2}$ | $\mathrm{~J}_{3}$ | $\mathrm{~J}_{4}$ | $\ldots$ |
| $\mathrm{M}_{1}$ | $\tau_{11}$ | $\tau_{12}$ | $\tau_{13}$ | $\tau_{14}$ | $\cdots$ |
| $\mathrm{M}_{2}$ | $\tau_{21}$ | $\tau_{22}$ | $\tau_{23}$ | $\tau_{24}$ | $\ldots$ |
| $\mathrm{M}_{3}$ | $\tau_{31}$ | $\tau_{32}$ | $\tau_{33}$ | $\tau_{34}$ | $\ldots$ |
| $\ldots$ | $\cdots$ | $\cdots$ | $\cdots$ | $\cdots$ | $\cdots$ |

The first operation of the first job has no dependencies from another operations, and it starts immediately; however, remaining operations depend on the previous operation in the same machine, the previous operation of the same job, or both (Figure 2). Indeed, PN modeling allows setting dependencies among operations and it is taken into advantage in order to define the operations sequence of the FSSP.

Fig. 2. Job operations dependency from previous operations of the same job, and/or previous operations performed in the same machine.

As we mentioned above, the first job is processed instantly in every machine as soon as the previous machine finishes. Similarly, the first machine processes all the operations as soon as the previous operation job is processed. In these cases, the operations have only one dependency and the accumulative time is the sum of the processing time for all the operations of the first job, or the sum for the operations processed in the first machine. However, the other operations take into account the maximum time from two previous operations, the previous operation in the same machine and the previous operation of the same job.

Once the job operations have been denoted as PN structures, it is important to link them in order to create a unique PN model representing the whole flexible manufacturing system.

Linking lines in figure 2 are represented as places connecting PN transitions for each job operation. Hence, any FMS with a number of shared machines and a number of jobs can be modeled by PNs as shown in figure 3.

Fig. 3. PN model representing the job operations of a FMS (figure 2), where processing time $\tau$ is stored in PN places.

For instance, Table 1 shows the processing times needed for three machines that will process four jobs. All jobs are processed in the same order in all machines. Every value represents the processing time $\tau$ needed by an operation $\mathrm{O}_{\mathrm{ij}}$. which belongs to a job $\mathrm{J}_{\mathrm{j}}$ and it is carried out in a machine $\mathrm{M}_{\mathrm{i}}$.

The PN model for this example is shown in figure 4. It contains twelve PN structures representing every job operation, an input place, an output place, and seventeen connecting places. Thus, the initial marking $\mathrm{M}_{0}$ is a vector with 31 elements, 30 of them are zero and the 13 th element is equal to 1 .

Fig. 4. PN model representing a FMS (figure 2), where processing time $\tau$ is stored in PN places. (a)

The TPPN model generated by the algorithm create_TPPN taking into account the job sequence order is shown in figure 4(a). For a different sequence order the PN structure is the same; however, the processing time values are assigned to different places, according to the desired order. For instance, for the job sequence order $\left[\begin{array}{lll}2 & 1 & 4\end{array}\right]$ the TPPN obtained is denoted in figure 4(b).

## 5. Algorithms

### 5.1. Algorithm utilized to create the $P N$ model

In this algorithm the PN model is created from the processing time data for every job processed in each machine. The output is the PN model that represents the FMS.

Algorithm create_TPPN
Input: $\tau_{i j}, ~ O S$
Output: PN

```
1. Initialize variables
place = 1
trans = 1
2. For i = 1 to NumberOfMachines
For j = 1 to NumberOfJobs
    Aout(trans,place) = 1
    trans = trans+1
    Ain(trans,place) = 1
    trans = trans+1
    place = place+1
```

End For
End For
3. For i $=1$ to NumberOfMachines
For $j=1$ to NumberOfJobs
if(i==1 \& \& j==1)
Ain(1,place) $=1$
pos = place;
place = place+1
elseif i==1
Aout $\left(2^{*}(j-1)\right.$, place $)=1$
Ain(2*j-1,place) = 1
place = place+1
elseif $j==1$
Aout (2* (i-2)*nj+2*j,place) $=1$
Ain(2*(i-1)*nj+1,place) $=1$
place = place+1
else
Aout (2* (i-2)*nj + 2*j,place) = 1
Ain(2*(i-1)*nj+2*j-1,place) = 1
place $=$ place +1
Aout ( $2 *$ nj* (i-1) $+2 *(j-1)$, place) $=1$
Ain(2*nj*(i-1) +2*j-1,place) = 1
place = place+1
End If
End For
End For
4. Aout (nt,place) $=1$
5. $\mathrm{PN}=$ Aout - Ain

In Step 1 the variables place and trans are initialized to 1. In Step 2, the PN structure for every operation $O_{i j}$ is created, it contains one place and two transitions. Next, in Step 3 the places to link the PN structures obtained in Step 2
are added to the PN model. In Step 4 the last place is connected to the PN. Finally, in Step 5, the PN is obtained from the subtraction of output arcs (Aout) minus input arcs (Ain).

### 5.2. Algorithm applied to calculate the makespan

Once the PN model is obtained, we are able to compute the makespan of the
FMS according to a job operation sequence. The algorithm to perform this calculus is the following.

Algorithm getMakespan
Input: PN, S, $M_{0}$, D
Output: Makespan

1. Initialize variables

Dacum $=\left[\begin{array}{lllll}0 & 0 & 0 & \ldots & 0\end{array}\right]$
2. For $i=1$ to NumberOfTransitions
// input places to $t_{i}$
ip $=\bullet \mathrm{t}_{\mathrm{i}}$
// output places from $t_{i}$
$o p=t_{i} \bullet$
$\max =-\infty$;
For $j=1$ to |ip| If Dacum(ip(j)) > max max $=\operatorname{Dacum}(i p(j)) ;$ End If
End For
For $\mathrm{k}=1$ to |op| Dacum (op(k)) = max $+\mathrm{D}(\mathrm{op}(\mathrm{k}))$;
End For
End For
3. Makespan $=$ Dacum (NumberOfPlaces)

In Step 1, the variable Dacum is initialized to a vector with zero values. This variable is utilized to accumulate the total time needed to perform all the operations. In Step 2, every enabled transition is fired, and the maximum accumulated time from its input places is taken and placed in the output place plus the corresponding time $\tau$. In Step 3 the accumulated time is assigned to the variable Makespan.

### 5.3. Example

For the job sequence $\left.\begin{array}{llll}1 & 2 & 3 & 4\end{array}\right]$, whose TPPN shown in figure 4(a), the calculus of the makespan is as follows. Vector D contains the processing times for every
machine in the system (figure 5a). At the beginning, Dacum has only zero values, and this vector has 31 elements. Starting the PN simulation by firing the enabled transition $t_{1}$, the value 96 is assigned to Dacum in the position of place $\mathrm{p}_{1}$. Next, the enabled transition $\mathrm{t}_{2}$ is fired and its firing assigns the value 96 to Dacum in the position of its output places $\mathrm{p}_{14}$ and $\mathrm{p}_{17}$. After that, enabled transition $t_{3}$ is fired, and the accumulative value in its input place $p_{14}(96)$ plus the processing time in $D$ in the position of its output place $p_{2}(\tau=74)$ is assigned to Dacum in the position of $\mathrm{p}_{2}(96+74=170)$.

All the transitions are fired in the same way, but in the case of two input places, the maximum accumulative time from both input places is considered for the sum of the total time.

In this example, the total time needed to process all the jobs is 379 time units, as shown in figure 5(b).

Fig. 5. (a) Vector D stores the time needed for every machine $M_{i}$ to process each job $J_{j}$. (b) Reachability tree denoting the evolution of vector Dacum depending on the fired transitions.

On the other hand, applying the algorithm getMakespan to the TPPN of figure 4(b) representing the job sequence $\left[\begin{array}{lll}2 & 1 & 4\end{array}\right]$, the total time required to finish all the jobs is 340 time units.

## 6. Conclusion

The nature of flexible manufacturing systems allows the use of shared resources; however, this versatility produces complications when the manufacturers think about the best sequence to process all the jobs. One of these is know as Flow Shop Scheduling Problem, which is a NP-hard problem that have been analyzed applying different kinds of techniques, such as exact models and heuristics strategies. One important calculus in the FSSP is the makespan value, which depends on the sequence of operations for each job and the order of machine utilization.

In this work we propose a timed place PN model to represent the processing times in a FMS with a number of jobs ready to be processed, and a number of machines utilized to process the jobs. Moreover, two algorithms are described. The first one is used to create the PN model from the time processing needed for each job operation. And the second algorithm obtains the total time required to finish all the jobs in a defined job sequence.

As further work, we are applying this PN representation in a heuristic method in order to find an acceptable job sequence to find a minimum makespan.
